Abstract

From 1980 through 1982 a significant increase in isolations of infectious hematopoietic necrosis virus (IHNV) from hatchery salmonids in the Columbia River basin was documented. Losses of cultured salmonids to the disease increased more than twentyfold from 1980 to 1981, and mortality-related losses were almost forty times that of 1980 levels during 1982. Extreme modifications of conventional hatchery practices have been adopted at certain locations where viral-infected stocks of fish must be used as a source for eggs. Because the virus is now widespread in the basin, personnel at locations with no previous history of IHNV must be especially alert to prevent its introduction.

Introduction

The viral etiology of infectious hematopoietic necrosis (IHN) disease of salmonid fish was established in 1958 (Wingfield et al., 1969). The virus, infectious hematopoietic necrosis virus (IHNV), was isolated and identified in tissue homogenates prepared from juvenile sockeye salmon undergoing an epizootic at Oakridge Salmon Hatchery located on Salmon Creek, a tributary of the Willamette River in Oregon. Previous evidence for the viral nature of what is believed to have been the same disease was reported as early as 1953 (Rucker et al., 1953). This also involved juvenile sockeye salmon at a Columbia River basin (CRb) hatchery (Leavenworth National Fish Hatchery in the state of Washington). Since those early observations the presence of the virus has been confirmed in fish at certain locations in the CRb and in other areas of the western United States, western Canada, Alaska and Japan. Amend et al. (1969) proposed the disease be named infectious hematopoietic necrosis, and this designation has gained wide acceptance. The impact of the virus in the CRb appeared to have declined coincidentally with the decrease in sockeye salmon production during the 1960s. During the decade of the 1970s, the virus was isolated sporadically at only a few CRb hatcheries. An exception was Round Butte Hatchery in central Oregon, where IHNV is enzootic (Mulcahy et al., 1980).

Epidemiology

From 1980 (Table 1) to 1981 (Tables 2 and 3) an alarming increase in the incidence of IHNV in fish at CRb hatcheries was observed. The data concerning isolations of IHNV in the CRb during 1982 (Tables 4 and 5) confirm that the virus has become more widely disseminated. The increase was apparent by the number of locations where the virus was detected in adult (carrier) fish (Tables 2 and 4) and by the occurrence of epizootics amoung juveniles (Tables 3 and 5). Most important was that from 1980 to 1982 thirteen hatcheries reported IHNV among stocks of fish for the first time. The trend during 1982 continued with observations of the virus at stations first reporting it during 1980 and 1981. This indicated the establishment of the agent in fish stocks at these locations.

Estimated losses of fish to the viral disease increased more than twentyfold from 1980 to 1981, and losses increased

almost fortyfold from 1980, during 1982 (Table 6). The
magnitude of these losses were such that fish production
quotas were not met at certain facilities. These were
primarily rainbow and steelhead trout hatcheries where
mortality among this species was devastating. The widespread
dissemination and increased occurrence of the virus in the
CRb (Figure 1) pose a serious threat to susceptible species
reared throughout the system.

Speculation concerning the mechanisms that lead to the
rapid spread of IHNV in the CRb was the subject of a recent
report (Groberg, 1983). A precise determination of the
event(s) that caused this situation would require intensive
laboratory and epidemiological investigations. It is
important that the reader realize a serious, nontreatable,
infectious disease problem now confronts fish culturists
throughout the CRb.

Life History

Fish culturists should be alert for the rapid onset of
excessive mortality, associated with signs of IHN disease
among alevins and young fish (Pilcher and Fryer, 1980).
Acute mortality in young fish has been the most common form
of the disease. Unpublished reports of IHNV isolations from
yearlings and smolts have become more frequent, however, and
these isolations are typically associated with an insidious,
chronic type of loss. This chronic form is probably not the
result of recent virus infection but more likely involves
fish infected when they were young. In addition, where IHNV
was recovered from larger fish, other infectious agents
and/or severe stress factors were present. Under these
conditions, it is difficult to determine if IHNV was the
direct or sole cause of the chronic loss.

As indicated (Tables 1-5), IHNV isolation was most often
made from asymptomatic, adult carriers or from juveniles with
IHN disease. Between the time infected fish grow to about
one gram in weight and reach sexual maturity as adults, the
virus apparently resides in the tissues of carrier fish in a
latent or eclipse phase (Amend, 1975). Present methods for
virus recovery do not allow detection during the eclipse
phase in carrier fish. When virus is detected in adult fish
at spawning, a management decision must be made concerning
the disposition of eggs derived from the carrier brood.
Because there is circumstantial evidence for vertical
transmission of virus from one or both parents (Carlisle,
Schat and Elston, 1979; Pilcher and Fryer, 1980), destruction
of potentially infected eggs is recommended by many
pathologists. However, other factors may be involved in
these decisions; infectious disease may not always be the
primary consideration. Similar decisions are required when

2

the disease occurs in young fish. Destruction of infected lots is a biologically sound practice because a portion of survivors become lifelong carriers and release infectious virus only as they approach sexual maturity (Amend, 1975). Therefore, transmission of virus from carrier fish can be prevented only by the elimination of carrier fish and eggs derived from them. While this approach seems drastic, avoidance represents the only known method of control for IHN.

Methods for Control

The prevalence of IHNV in the CRb has profoundly affected fish cultural practices at certain hatcheries where infected or carrier stocks must be used. All current procedures available for control of IHN are avoidance measures designed to prevent transmission of virus from infected or carrier fish to eggs or uninfected fish. It must be emphasized, however, that many of these control methods for IHNV are unproven. Examples of avoidance measures or modifications of conventional spawning and egg incubation methods are (1) fertilization of eggs from a single female with sperm from a single male (mating pair), (2) iodophor disinfection of eggs (Wood, 1974) from individual mating pairs during or after water hardening, (3) incubation of eggs from each mating pair using a separate, fish pathogen-free water source and (4) viral examinations of each fish spawned and only progeny from mating pairs in which virus cannot be detected are maintained and reared. Early rearing of fish, when they are highly susceptible to IHNV, in small groups affords an additional precaution. This concept is based on the fact that the disease may occur in some groups but will not occur in all, leaving these fish for production. Infected lots are destroyed to eliminate potential carriers. It is obvious that an excess of eggs must be taken to accommodate the anticipated loss and thus insure the amount required for production.

Several other avoidance considerations are required to prevent epizootics or introduction of IHNV into hatcheries with no history of the virus. Infectious hematopoietic necrosis is a contagious disease and therefore, carrier fish in a hatchery water supply serve as a reservoir of virus for hatchery fish. Carrier fish must be eliminated from the water source or the water must be freed of infectious virus (disinfected) to prevent waterborne transmission of the virus to fish in the hatchery. Transfers of eggs or fish into a virus-free facility should be made only if the parent stock has a documented history (viral inspections over a 3-5 year period) indicating with high probability that the brood stock are not infected or carrying the virus. The watershed from

which transferred fish come should be evaluated as part of this disease history. Any egg transfers from facilities in the CRb to areas where IHNV does not occur must now be regarded as a high-risk practice. When transfers are made, they should involve only eggs from adults which have been inspected and incubated in pathogen-free water. Fish culturists should insist upon prior sanitation of any fish transport equipment and trucks, tagging equipment, grading devices and other paraphernalia brought into their facility. Sanitary practices (Amend and Conte, 1982) within the hatchery should also be strictly followed to limit the spread of disease if outbreaks occur amoung fish in a limited number of ponds.

Indications are that IHN will continue to pose a severe threat to fish in the CRb. Personnel at hatcheries with no previous history of IHN will have to be particularly alert to prevent introduction of the virus into their facilities. Spawning stocks and water supplies must be kept free of infected or carrier fish, and sanitation of equipment coming into a hatchery should be insisted upon. Fish culture by conventional methods is probably impractical at stations where infected stocks are present and must now be used for production. Extreme measures such as those identified in this report may be the only means now available to successfully rear fish at these locations.
